ABSTRACT

Background

We aimed to compare differences in risk and timing of recurrent ischemic events among patients with stable ischemic heart disease (SIHD), non–ST-segment elevation acute coronary syndrome (NSTEMI), and ST-segment elevation myocardial infarction (STEMI) undergoing percutaneous coronary intervention (PCI).

Methods

We performed an individual data pooled analysis of 5 randomized controlled all-comer trials including a total of 8,859 patients and investigated the risk and timing of recurrent ischemic events among patients with SIHD (n = 3,543), NSTEMI (n = 3,364), and STEMI (n = 1,952) throughout 2 years of follow-up.

Results

At 2 years, all-cause mortality was higher among patients with STEMI (6.4%) and NSTEMI (6.1%) compared with those with SIHD (4.2%) (STEMI vs SIHD: hazard ratio [HR] 1.40, 95% CI 1.09-1.78, P =

.007; NSTEMI-ACS vs SIHD: 1.40, 95% CI 1.13-1.73, $P = .002$). In a landmark analysis, the risk of mortality among patients with STEMI compared with those with SIHD was confined to the first 30 days after PCI (HR 6.19, 95% CI 3.15-12.16, $P < .001$) but was similar between 30 days and 2 years (HR 1.00, 95%CI 0.76-1.33, $P = .974$) ($P_{\text{interaction}} < .001$). Conversely, patients with NSTEMI-ACS had a higher risk of mortality compared with those with SIHD both within the first 30 days (HR 2.19, 95%CI 1.08-4.47, $P = .031$) and beyond (HR 1.34, 95%CI 1.07-1.67, $P = .012$) ($P_{\text{interaction}} < .001$). A similar pattern in the differential timing of events was observed for cardiac death. Beyond 30 days, the risk of myocardial infarction was comparable in patients with STEMI and SIHD, whereas the risk in patients with NSTEMI-ACS was increased (HR 1.65, 95% CI 1.23-2.21, $P = .001$).

Conclusion

Whereas patients with NSTEMI-ACS are at increased risk for death at any time after PCI, the mortality of STEMI patients is higher during the first 30 days after PCI but not thereafter compared with patients with SIHD. (*Am Heart J* 2016;175:56-65.).

METHODS

Study population

We pooled individual patient data from 5 randomized controlled trials conducted between 2003 and 2014 including a total of 8,859 patients: the sirolimus-eluting and paclitaxel-eluting stent for coronary revascularization (SIRTAX) trial (n = 1,012),⁸ the biolimus-eluting stent with biodegradable polymer versus sirolimus-eluting stent with durable polymer for coronary revascularisation (LEADERS) trial (n = 1,707),⁹ the comparison of zotarolimus-eluting and everolimus-eluting coronary stents (RESOLUTE All Comers) trial (n = 2,018),¹⁰ the prolonging dual antiplatelet treatment after grading stent-induced intimal hyperplasia study (PRODIGY) (n = 2,003),¹¹ and the comparison of ultrathin strut biodegradable polymer sirolimus-eluting stents versus durable polymer everolimus-eluting stents (BIOSCIENCE) trial (n = 2,119).¹² Broad inclusion criteria were applied in all included trials consistent with an all-comers study design. Details of the individual trials have been published elsewhere.⁸⁻¹² The trials complied with the Declaration of Helsinki and were approved by the ethics committee of each study site. All patients provided written informed consent for participation in the study. No extramural funding was used to support this work. The authors are solely responsible for the design and conduct of this study, all study analyses, the drafting and editing of the paper, and its final contents.

Procedures

Balloon angioplasty and stent implantation were performed according to standard techniques and guidelines current at the time of the study. Periprocedural anticoagulation was accomplished with unfractionated heparin or bivalirudin; the use of glycoprotein IIb/IIIa inhibitors was left to the discretion of the operator. Dual antiplatelet treatment consisted of acetylsalicylic acid of at least 75 mg daily and a P2Y₁₂-inhibitor in all trials, and was prescribed for at least 12 months in the SIRTAX, the LEADERS, and the BIOSCIENCE trials^{8,9,12} and for at least 6 months in the RESOLUTE All Comers trial.¹⁰ In the PRODIGY trial, patients were randomized at 30 days in a balanced fashion to either 6 or 24 months of dual antiplatelet treatment.¹¹ Among patients treated with bare metal stents for SIHD, clopidogrel discontinuation was allowed at any time beyond 30 days.

Definitions

The primary end point of the present analysis was all-cause mortality. Secondary end points were cardiac death, MI, definite stent thrombosis, and definite and probable stent thrombosis according to the Academic Research Consortium criteria.¹³ End point definitions were comparable across the 4 trials included in the present analysis and consistent with the definitions proposed by the Academic Research Consortium¹³ in the majority of trials.

Cardiac death was defined as death from cardiac causes or any death from unknown causes in SIRTAX, LEADERS, and BIOSCIENCE,^{8,9,12} and as any death unless an undisputed noncardiac cause was present in the RESOLUTE All Comers trial.¹⁰ Myocardial infarction was defined in SIRTAX and LEADERS as the presence of new Q waves in at least 2 contiguous leads and an elevated creatine kinase–MB fraction or—in the absence of significant Q waves—as an increase in the creatine kinase level to more than twice the upper limit of the reference range with an elevated level of creatine kinase–MB or troponin.^{8,9} In the RESOLUTE All Comers and the BIOSCIENCE trials, myocardial infarction was defined according to an “extended historical” definition consistent with the one used in SIRTAX and LEADERS.¹⁰ In PRODIGY, the definition of myocardial infarction was based on the detection of increase and/or decrease in creatine kinase–MB or troponin with at least 1 value above the upper limit of normal together with evidence of myocardial ischemia with at least 1 of the following: symptoms of ischemia, electrocardiographic changes indicative of new ischemia (new ST-T changes or new left bundle-branch block), and development of pathological Q waves.¹¹

Statistical analysis

The baseline and procedural characteristics are presented as means \pm SD in case of continuous variables and as frequencies and percentages in case of categorical variables. The P values for differences across groups are from χ^2 tests, linear regression (baseline characteristics), or Poisson regression (procedural characteristics). The clinical outcomes at 30 days, 1 year, and 2 years are presented as counts using Kaplan-Meier incidence rate and illustrated as cumulative incidence both with and without landmark analysis at 30 days. We present both crude and adjusted hazard ratios

(HRs) for the clinical outcomes at 30 days, 1 year, and 2 years. We adjusted for age, gender, body mass index, diabetes, hypertension, hypercholesterolemia, previous MI, glomerular filtration rate, left ventricular ejection fraction, and type of stent. The difference across groups was estimated from Cox regressions. We refrained from stratifying the analyses according to stent type. All hypotheses were 2-sided, and a P value < .05 was deemed statistically significant. All tests of differences across groups take into account the cluster effect of the trials. The statistical analyses were performed with Stata (version 13.1).

RESULTS

Among 8,859 patients enrolled in 5 trials, 3,543 patients (40%) presented with SIHD, 3,364 with NSTEMI-ACS (38%), and 1,952 with STEMI (22%). Two-year clinical follow-up was complete in 8,673 patients (98%). Baseline clinical characteristics are summarized in Table I. Patients presenting with SIHD and NSTEMI-ACS had a similar cardiovascular risk profile. In contrast, STEMI patients less frequently had diabetes (14% vs 27%, $P < .001$), hypertension (53% vs 73%, $P < .001$), or hypercholesterolemia (44% vs 73%, $P < .001$) as compared with patients with SIHD. Along the same line, patients with NSTEMI-ACS and SIHD more commonly had a history of previous MI and previous revascularization procedures. Both patients with STEMI ($47\% \pm 11\%$) and NSTEMI-ACS ($55\% \pm 11\%$) had a lower systolic left ventricular ejection fraction compared with patients with SIHD ($58\% \pm 11\%$) ($P < .001$ and $P = .006$, respectively). Procedural characteristics are shown in Table II. Patients with STEMI had fewer lesions as compared with patients with SIHD (1.4 ± 0.7 vs 1.5 ± 0.8 , $P < .001$); moreover, we observed a trend toward a lower number of vessels treated per patient among patients with STEMI as compared with patients with SIHD (1.2 ± 0.5 vs 1.3 ± 0.5 , $P < .001$).

Tables IIIA and IIIB summarize crude and adjusted clinical outcomes at 30 days, 1 year, and 2 years, respectively. All-cause mortality at 30 days amounted to 2.2% among patients with STEMI, 0.7% among patients with NSTEMI-ACS, and 0.3% among patients with SIHD (STEMI vs SIHD adj HR 7.36, 95% CI 2.83-19.13, $P < .001$; NSTEMI-ACS vs SIHD adj HR 2.65, 95% CI 1.050-6.67, $P = .038$). At 2 years, all-cause mortality among patients with STEMI, NSTEMI-ACS, and SIHD was 6.4%, 6.1%, and 4.2%,

151 respectively (STEMI vs SIHD adj HR 1.54, 95% CI 1.12-2.11, $P = .007$; NSTE-ACS vs SIHD adj HR 1.37,
152 95% CI 1.06-1.78, $P = .018$) (Figure 1, A). In a landmark analysis shown in Figure 1, B and Table IV, the
153 risk of all-cause mortality was increased among patients with STEMI as compared with those with SIHD
154 within the first 30 days after PCI (HR 6.19, 95% CI 3.15-12.16, $P < .001$) but was similar between 31
155 days and 2 years (HR 1.0, 95% CI 0.76-1.33, $P = .974$) (P for interaction $< .001$). In contrast, patients
156 with NSTE-ACS had a higher risk of all-cause mortality compared with those with SIHD both within the
157 first 30 days (HR 2.19, 95% CI 1.08-4.47, $P = .031$) and beyond (HR 1.34, 95% CI 1.07-1.67, $P = .012$). A
158 similar pattern in the differential timing of events among patients with STEMI, NSTE-ACS, and SIHD
159 was observed for cardiac death (Figure 2, A and B; Table IV).

160 Myocardial infarctions occurred less frequently among patients with STEMI as compared with SIHD
161 throughout 2 years of follow-up (5.1% vs 7.2%, adj HR 0.58, 95% CI 0.43-0.78, $P = .001$). The difference
162 was driven by a lower incidence of MI among patients with STEMI within the first 30 days (HR 0.38,
163 95% CI 0.28-0.53, $P < .001$), whereas no difference was documented for the time between 30 days and
164 2 years (HR 1.00, 95% CI 0.69-1.44, $P = .980$) (Figure 3, Table IV). There was no significant difference
165 in the rate of MIs among patients with NSTE-ACS as compared with SIHD overall (9.0% vs 7.2%, adj HR
166 1.12, 95% CI 0.94-1.32, $P = .197$). However, there was a higher risk of MI in the period from 31 days to
167 2 years among patients with NSTE-ACS as compared with SIHD (HR 1.65, 95% CI 1.23-2.21, $P = .001$)
168 (Table IV).

169 Rates of definite stent thrombosis amounted to 2.3%, 1.4%, and 1.3% among patients with STEMI,
170 NSTE-ACS, and SIHD, respectively (STEMI vs SIHD adj HR 1.92, 95% CI 1.25-2.92, $P = .003$; NSTE-ACS vs
171 SIHD adj HR 1.10, 95% CI 0.73-1.67, $P = .652$). In a landmark analysis with the landmark at 30 days, the
172 increased risk of stent thrombosis among STEMI patients as compared with patients with SIHD was
173 confined to the first 30 days (HR 2.54, 95% CI 1.45-4.43, $P = .001$), whereas the subsequent risk was
174 comparable (HR 1.27, 95% CI 0.65-2.48, $P = .482$) (Figure 4, Table IV). There was no difference in the
175 risk of stent thrombosis between patients with NSTE-ACS or SIHD within 30 days (HR 1.01, 95% CI 0.56-
176 1.84, $P = .961$) and beyond (HR 1.18, 95% CI 0.66-2.12, $P = .577$). The findings were consistent in crude
177 and adjusted analysis, respectively (Table IV).

DISCUSSION

In the present individual data pooled analysis of 5 randomized controlled all-comer trials, we observed a differential in timing of ischemic events according to presentation with STEMI, NSTEMI, or SIHD. The principal findings of our analysis can be summarized as follows: (1) Patients with NSTEMI and SIHD had a comparable risk profile at baseline, whereas patients with STEMI had a lower prevalence of cardiovascular risk factors and less frequently had a history of prior cardiovascular disease. (2) Patients with STEMI had a lower risk of recurrent MI compared with patients with SIHD throughout 2 years of follow-up. Although the risk of MI among patients with NSTEMI and SIHD was comparable throughout 2 years, we observed an increased risk of MI beyond the periprocedural period among patients with NSTEMI as compared with those with SIHD. (3) The increased risk of 30-day mortality among patients with STEMI as compared with those with SIHD was no longer apparent beyond 30 days of follow-up. In contrast, patients with NSTEMI had an increased risk of death as compared with those with SIHD which was sustained during the entire time of follow-up.

Patients undergoing PCI for NSTEMI or SIHD were found to have a similar prevalence of cardiovascular risk factors and comparable rates of previous revascularization procedures. In contrast, patients with STEMI were characterized by a lower rate of cardiovascular risk factors and fewer previous cardiac revascularization procedures. Moreover, patients with STEMI tended to be younger compared with patients with SIHD or NSTEMI and had fewer coronary lesions. STEMI may often represent the first manifestation of cardiovascular disease and results from rupture of vulnerable plaques without underlying significant coronary stenosis. Conversely, NSTEMI and SIHD referred for PCI may indicate advanced stages of disease with a higher number of lesions with hemodynamically significant stenosis and more gradual clinical manifestation. Absence of previous medical contacts in patients presenting with STEMI as a first manifestation of coronary artery disease may be associated with a higher rate of underdiagnosed risk factors and may have increased the risk of acquisition bias.

Patients undergoing PCI for NSTEMI were at highest risk to experience a recurrent MI within the subsequent 2 years, followed by patients with SIHD and STEMI, respectively. Several reasons may account for this finding. A low rate of recurrent MI may be related to ascertainment bias due to

differences in definition related to periprocedural MI in the setting of STEMI as compared with SIHD; whereas the risk of recurrent MI among patients with STEMI was low within the first 30 days after PCI, a landmark analysis showed no significant difference in rates of MI beyond the periprocedural period. In addition, the increased risk of recurrent MI may be related to a higher atherosclerotic burden and therefore more advanced CAD among patient with NSTEMI-ACS and SIHD as compared with patients with STEMI. However, an increased risk of MI beyond the periprocedural period among patients with NSTEMI-ACS as compared with those with SIHD calls for an additional explanation. Progression of disease may be related to culprit or nonculprit lesions¹⁴. The inflammatory milieu in patients with acute coronary syndromes has been associated with generalized plaque vulnerability not limited to the culprit lesion. Healing of ruptured plaques stimulates progression of luminal narrowing and propels coronary artery disease.¹⁵ Indeed, a recent experimental study in mice suggests that acute MI accelerates atherosclerosis by activating the chronic inflammatory disease process.³ This mechanism may be responsible for recurrent MIs in nonculprit lesions. Furthermore, intravascular imaging studies of culprit lesions have suggested a delayed healing response among patients with acute coronary syndromes as compared with those with SIHD that was attributable to baseline lesion characteristics.¹⁶ The latter in turn may increase the risk for repeat MIs related to the culprit vessel.

The risk of definite stent thrombosis was highest among patients presenting with STEMI, largely driven by more than 2-fold increased risk of stent thrombosis within the first 30 days after PCI in patients with STEMI as compared with SIHD. This finding is likely explained by the prothrombotic milieu of acute MI and is consistent with existing literature.

After 2 years of follow-up, patients with STEMI and NSTEMI-ACS had numerically comparable mortality rates that were 1.5 times higher than in patients with SIHD. A similar pattern was observed across the 3 groups for cardiac mortality. However, we observed an important differential in timing of all-cause and cardiac mortality. An increased risk of death within the first 30 days after STEMI was offset between 30 days and 2 years compared with patients with SIHD. In contrast, patients with NSTEMI-ACS experienced an increased risk of death compared with patients with SIHD irrespective of time after the intervention. Our findings are consistent with previous reports. In an analysis of 4,387 patients in

the United States, patients with STEMI had a higher adjusted mortality risk during the first 2 months as compared with patients with NSTEMI-ACS (adj HR 1.85, 95% CI 1.45-2.38) and a lower risk of mortality beyond 2 months (adj HR 0.68, 95% CI 0.59-0.83). However, rates of index revascularization were rather low and amounted to 75% among patients with STEMI and 56% among patients with NSTEMI-ACS, respectively.⁵ Adverse long-term outcome among patients with NSTEMI-ACS as compared with patients with STEMI has been associated with a higher prevalence of comorbidities, a greater extent of coronary artery disease, and lower rates of revascularization.⁵ More recent data from South Korea corroborated these findings in >28,000 patients with STEMI or NSTEMI-ACS. Whereas the rates of major adverse cardiovascular events and cardiac mortality were higher in patients with STEMI as compared with patients with NSTEMI-ACS within the first 30 days (6.9% vs 4.5%, $P < .001$), reverse event rates were observed during the time period between 30 days and 2 years (STEMI 8.0% vs NSTEMI-ACS 9.1%, $P = .007$). Risk factors for both early and late cardiac death in patients with STEMI or NSTEMI-ACS were reduced left ventricular ejection fraction and clinical signs of congestive heart failure according to Killip class.⁶ In another analysis of 13,441 patients in Poland, an adverse long-term prognosis observed in patients with NSTEMI-ACS as compared with patients with STEMI was offset after adjustment for baseline characteristics and treatment strategy.⁷ In contrast to the above-mentioned reports, all patients included into the present analysis underwent PCI, hence eliminating the potential confounder of revascularization.

The present analysis has several limitations. First, only patients undergoing PCI were included in the present analysis, which introduces a selection bias, particularly among patients with SIHD. Patients with SIHD undergoing conservative management are not represented in the present analysis. In turn, revascularization has been identified as a confounder in previous analyses comparing patients with STEMI and NSTEMI-ACS only. Second, there were some minor differences in definitions of adverse events across trials. In particular, the assessment of periprocedural MIs may have been more difficult among patients with ongoing MI. In contrast, all patients were included into randomized controlled trials with a high data quality, meticulous follow-up, and independent event adjudication. Third, the combination of 5 all-comer trials performed during a time span of 10 years may be confounded by differences in

temporal trends in revascularization therapy and optimal medical treatment. No comprehensive information on medical management and adherence to secondary prevention after PCI was available. Prolonged duration of dual antiplatelet treatment beyond 1 year or combination with novel P2Y₁₂ ADP-receptor antagonists might have decreased the number of ischemic events. Fourth, in view of a noticeable gradient of risk across all ischemic outcomes, the absence of a significant difference between patients with STEMI or SIHD in our analysis may reflect a lack of power. And finally, clinical follow-up was limited to 2 years. We do not know to what extent the results can be extrapolated to long-term clinical follow-up.

CONCLUSION

The risk and timing of recurrent ischemic events differ importantly between patients with STEMI, NSTEMI-ACS, and SIHD after PCI. Whereas patients with NSTEMI-ACS are at increased risk for death at any time after PCI, the mortality of STEMI patients is increased during the first 30 days after PCI but not thereafter compared with patients with SIHD.

The authors report no conflict of interest related to the content of this article.

IMPACT ON DAILY PRACTICE

The findings of the present study show a time variable pattern of recurrent events following PCI according to presentation with SIHD, NSTEMI-ACS, or STEMI, respectively, which may have important implications for long-term medical management and secondary prevention.

Table II

Procedural characteristics. Depicted are means ± SD with P values from Poisson regression or counts (percentage) with P values from χ^2 tests. All tests take into account the clustering of patients in trials.

	STEMI n = 1952	NSTE-ACS n = 3364	SIHD n = 3543	Overall P value	P value STEMI vs SIHD	P value NSTE-ACS vs SIHD
No. of lesions per patient	1.4 ± 0.727	1.5 ± 0.790	1.5 ± 0.767	<.001	<.001	.444
No. of vessels treated per patient	1.2 ± 0.459	1.3 ± 0.509	1.3 ± 0.492	<.001	<.001	.378
Multivessel intervention	334 (21.0%)	857 (30.9%)	865 (30.9%)	<.001	<.001	.979
<i>Target vessel</i>						
Right coronary artery	827 (42.4%)	1157 (34.4%)	1304 (36.8%)	<.001	<.001	.149
Left main	38 (1.9%)	118 (3.5%)	117 (3.3%)	.001	.028	.837
Left anterior descending	1005 (51.5%)	1728 (51.4%)	1775 (50.1%)	.424	.963	.190
Left circumflex	438 (22.4%)	1167 (34.7%)	1125 (31.8%)	<.001	<.001	.001
Bypass graft	5 (0.8%)	103 (3.1%)	117 (3.3%)	<.001	<.001	.779
<i>Type of stent</i>						
Bare metal stent	180 (9.2%)	211 (6.3%)	111 (3.1%)	<.001	.002	<.001
Paclitaxel-eluting stent	256 (13.1%)	365 (10.9%)	388 (11.0%)	.354	.174	.968
Early-gen. sirolimus-eluting stent	257 (13.2%)	473 (14.1%)	623 (17.6%)	.401	.769	.233
New-gen. sirolimus-eluting stent	211 (10.8%)	366 (10.9%)	486 (13.7%)	.159	.964	.096
Biolimus-eluting stent	135 (6.9%)	335 (10.0%)	387 (10.9%)	.015	.005	.545
Everolimus-eluting stent	561 (28.7%)	983 (29.2%)	1035 (29.2%)	.978	.832	.997
Zotarolimus-eluting stent	352 (18.0%)	631 (18.8%)	513 (14.5%)	.068	.855	.021

Table IIIA:

Clinical outcomes at 30 days, 1 year, and 2 years (crude analysis). Depicted are counts (Kaplan-Meier incidence rates %). Hazard ratios (95% CI) and P values are from Cox regressions taking into account the trial effect.

	STEMI n =1952	NSTE-ACS n =3364	SIHD n =3543	STEMI vs SIHD		NSTE-ACS vs SIHD	
				Crude HR (95% CI)	P value	Crude HR (95% CI)	P value
<i>At 30 d</i>
